 (Dated: February 25, 2008)

Low temperature (10K) high voltage bias dynamic conductivity (up to 2.7V) and shot noise (up to 1V) were studied in epitaxial Fe(100)/Fe-C/MgO(100)/Fe(100) magnetic tunnel junctions, as a function of the magnetic state. The junctions show large tunnel magnetoresistance (185% at 300K and 330% at 4K). Multiple sign inversion of the magnetoresistance is observed for bias polarity when the electrons scan the electronic structure of the bottom Fe-C interface. The shot-noise shows a Poissonian character. This demonstrates a pure spin dependent direct tunneling mechanism and validates the high structural quality of the MgO barrier.

PACS numbers:

Magnetic tunnel junctions (MTJs)[1, 2] are nowadays one of the most active areas of material science and spintronics. Recent theoretical predictions[3, 4] and experimental demonstration[5, 6, 7, 8, 9] of coherent spin-dependent tunneling in single crystal Fe(100)/MgO(100)/Fe(100) MTJs revolutionized this area providing new ways to create devices with room temperature Tunneling Magneto-Resistance (RT-TMR) exceeding 100%. The large TMR at low bias is mostly due to fully spin polarized Δ_1 bulk electron states in Fe(001), reflected for antiparallel ferromagnetic electrodes configuration (AP) or well transmitted for the parallel (P) state[3, 4]. However, the tunneling mechanism gets more complex when taking into account the electronic structure of the interfaces[10] and when biasing the junction. Therefore, for finite bias polarities the antiparallel conductance may exceed the parallel one, resulting in TMR suppression[8] or its sign reversal[10]. By engineering the chemical and electronic structure of the Fe/MgO interface, the voltage variation of the TMR in amplitude and sign can be skilfully manipulated. It has been recently demonstrated that the carbon-doping of the bottom Fe/MgO interface leads to strongly asymmetric TMR vs bias, providing a root for creation of high-output voltage device applications[9].

Our Letter presents a first study of dynamical conductance and TMR in a large bias window, up to 2.7 V, for Fe(100)/Fe-C/MgO(100)/Fe(100) MTJs. The shot noise analysis in different magnetization configuration is performed at voltages up to 1V. The experiments are done at room temperature (300K) and low temperature (4K-10K). The measured TMR ratio increases from 185% at 300K to 330% at 4K, mostly due to the strong temperature variation of the tunnel conductivity in the antiparallel (AP) state. Moreover, our tunneling spectroscopy experiments show a clear maximum in the AP conductivity for a finite bias and a multiple TMR sign inversion. These experiments demonstrate the role of the minority spin Fe interface resonance state (IRS) to the tunneling. Furthermore, in both parallel (P) and antiparallel magnetization configuration, the shot noise measurements demonstrate an uncorrelated direct tunneling mechanism across the MgO barrier. The shot noise analysis and the large breakdown voltage of the junctions (up to 3V) demonstrates the high quality of our MgO barriers (i.e. absence of defects such as oxygen vacancies).

Our epitaxial Fe(45nm)/ MgO(3nm)/ Fe(10nm)/ Co(20nm)/ Pd(10nm)/ Au(10nm) samples were grown by molecular beam epitaxy (MBE) on MgO(100) substrates under UHV condition (4×10^{-11} mbar base pressure). Different coercive field of the MTJ electrodes is obtained by hardening the top bcc Fe electrode with hcp Co epitaxially grown with in-plane c axis. Prior to deposition, the substrate is annealed at 600°, then the layers are grown at room temperature. For flattening, the Fe electrodes are annealed to 450° (bottom Fe) and 380° (top Fe). Following the growth procedure[13], two different samples can be grown: samples with clean Fe/MgO bottom interfaces and samples with carbon doping at bottom Fe/MgO interface (Fe/Fe-C/MgO). The Reflection High-Energy Electron Diffraction (RHEED) analysis performed on each layer of the MTJ stack allows a direct control of the epitaxial growth and the high crystalline quality of the epitaxial layers. Within the pseudomorphical growth regime, the two-dimensional layer-by-layer growth of the MgO barrier is monitored by the intensity oscillations in the RHEED patterns. Compared to clean samples, in the samples with carbon the bottom Fe(001) electrode presents a $c(2 \times 2)$ surface reconstruction, as shown by the RHEED picture (Fig. 1). After the growth of the multilayer stack, MTJs with micrometric lateral size have been patterned using standard optical lithography/ ion etching process. All the MTJs studied here contain carbon doped Fe/MgO interface. They have shown a large voltage stability, up to 3 Volts.

Dynamic conductance $G(V)$ and shot-noise bias dependence have been studied using four-probe method with a set-up allowing to vary the temperature between 2 and 300K, equipped with preamplifiers situated on top of the cryostat. Two different techniques were employed to measure dynamic conductance in P or AP states, providing nearly identical results. The first one uses a current-voltage ($I - V$) converter and a voltage amplifier. In this case, the MTJ is biased using a constant DC voltage with superimposed low amplitude sinusoidal wave ($V_{AC} < 20mV$). The voltage drop on the junctions and the current were obtained by using an analogue-digital converter (ADC) and a lock-in amplifier, providing the dynamic conductance. The second technique, mainly employed at high bias, uses square current wave of current superimposed on DC current. Shot noise measurements were done using a cross-correlation technique. More details of experimental setup were published elsewhere[11, 12].

At 300K, the Fe/Fe-C/MgO(3nm)/Fe/Co MTJs show $R \times A$ product values (RT) ranging from 0.42 to 0.48 $M\Omega \cdot \mu m^2$. The inset in the top panel of Fig. 2 shows typical TMR curves measured at 10mV either at 300K and at 4K. The large TMR ratio of 185% at 300K indicates the high quality of the MTJs. Interestingly, the low temperature TMR ($\sim 330\%$) notably exceed previously reported (250%) maximum values of zero-bias TMR in epitaxial Fe(100)/MgO/Fe MTJs with 'undoped' Fe/MgO interfaces[8]. The temperature variation of the TMR is understood from the dynamic conductivity experiments $G = dI/dV$ shown in Fig. 2(a) which plots $G(V)$ at 300 and 10K within a voltage range of 0.8V. Firstly, asymmetric $G(V)$ characteristics in positive and negative voltage demonstrate different electronic structure of the top and bottom electrodes and Fe/MgO interfaces[9]. Secondly, we remark significantly different temperature variation of conductivity in P and AP magnetization configurations. In the AP configuration (Fig. 2(b) bottom panel), we remark almost no temperature dependent shape variation, except the enhancement of low bias anomaly at 10K. However, we notice a strong reduction of $G_{AP}(V)$ by 50% at low temperature. On the other hand, a net temperature dependent shape variation between 300K and 10K (Fig. 2(a) top panel) is clearly seen for $G_P(V)$. Interestingly, the zero bias G_P is mostly constant with temperature (only 2% variation). Additional local minima appear at 10K for both positive and negative finite bias voltage. At low temperature, all studied MTJs reveal novel P-state low-bias conductance oscillations with about 4 minima (top panel of Fig. 2). We note that low-bias conductivity minima in the P state have been already observed in carbon free samples even at 300K. However, we always measured only two local conductance minima[13]. These minima were explained by the Δ_5 majority electron contribution to the total conductivity at low voltage ($< 0.3eV$ which is the top of the majority Δ_5 band (Fig. 2(b)). The origin of low temperature $G_P(V)$ minima observed in Fe/Fe-C/MgO/Fe MTJs opens interesting theoretical perspectives. These calculations should investigate in detail the effect of the realistic electronic structure of the Fe/Fe-C/MgO (i.e. effects of Fe-C bounding) on the tunneling, in the low bias regime.

Figure 3(a) presents high bias conductance for voltages up to 2.7V, measured at 10K. The influence of Joule heating (few K) on the $I - V$ s is neglected due to the rather weak observed low temperature temperature dependence of both G_P and G_{AP} . Interestingly, while $G_P(V)$ is rather symmetric, in negative voltage when the electrons tunnel into the bottom Fe-C/MgO electrode, the $G_{AP}(V)$ shows a strong asymmetric local maximum superimposed on roughly parabolic background. This 'local' resonant increase of the G_{AP} ($G_{AP} > G_P$) in a narrow[16] energy window will lead to the lower voltage sign reversal of the TMR (Fig. 3(a), Bottom panel). Similar to Scanning Tunneling Spectroscopy Experiments[14], and as we already previously shown[10], the resonant enhancement of G_{AP} is attributed to the contribution to the tunneling of the Fe minority interfacial resonance (IRS). However, we only observed this phenomena in carbon free Fe/MgO/Fe samples with thinner MgO barrier, where the Fe IRS still significantly contribute to the tunneling[15]. In the samples studied here, having carbon at the Fe-C/MgO interface, an important effect of the G_{AP} resonant activation by IRS is observed even for 3nm thick MgO barriers. To elucidate this interesting property, theoretical investigation of two effects is in progress: (i) the effect of Fe-C-MgO bounding on the minority spin Fe(001) IRS (i.e. shift in energy, dispersion in k); (ii) the carbon induced periodical perturbation of the potential at the bottom Fe/MgO interface (i.e. $c(2 \times 2)$ reconstruction, Fig. 1) induces scattering events which change k-vector. This has direct consequences on the total conductivity.

In positive bias, when electrons are injected toward the top electrode, the low bias TMR changes the sign above 1.5V. This is determined by the G_{AP} strong enhancement when, in the AP configuration the injected Δ_1 electrons from the bottom Fe electrode arrive as hot electrons in the top electrode and find an equivalent symmetry in the minority band. In negative voltage, when electrons tunnel into the bottom Fe-C/MgO electrode, similar contribution of the minority Δ_1 symmetry to the conductivity is expected. However, the TMR second sign reversal seems to appear at much higher voltages, above 2.5V (Fig. 3(a), bottom panel). One possible reason would be the reduction of the hot electrons thermalization length in the bottom electrode. The effect of the IRS at Fe-C/MgO interface on this phenomena requires further theoretical investigation.

Figure 3(b) presents shot noise measurements carried out at $T = 10K$ on Fe/Fe-C/MgO/Fe MTJs, with bias direction corresponding to injection of electrons from the top to the bottom (carbon doped) Fe/MgO interface. For comparison, the solid curves shows the 'theoretical' expectation for the shot noise, for electron tunneling having Poissonian character: $S_V = 2e < I > / G^2$ with G the dynamic conductivity (Fig. 3(a)) and I the applied current. Within the error bars, showing dispersion of the shot noise 'white' spectrum in the kHz range, the experimental data

clearly indicate the absence of electron correlations and/or sequential tunneling phenomena. This proves that both P and AP spin dependent conductance's and the shot noise are due to direct tunneling between electron bands, as expected for the coherent tunneling[17]. The absence of resonant assisted tunneling in the shot noise demonstrates the high quality of our epitaxial MgO barriers (i.e. the absence of oxygen vacancies). This high quality is furthermore confirmed by the large breakdown voltage of the MTJs (up to 3V).

The authors thank G. Lengaigne for technological process of MTJs and R.Villar for discussions and continuous support.

 - [15] The interfacial resonance state of Fe has a d_{z^2} orbital character and belongs to the Δ_1 symmetry. However, due to the strong localization of the d_{z^2} band, this state decays rapidly with the MgO thickness. Therefore, for large MgO thickness its contribution to the total AP conductivity is expected to be small.
 - [16] The spatial variation of the realistic electronic structure of the Fe-C/MgO interface (related to realistic morphology) will lead to a distribution in energy of the interfacial resonance.
